Muhammad Khushal Khan | Programming Supplement

MS in Applied Data Science, University of Chicago · Mean-reversion backtest with Monte Carlo bootstrap (Python)

Context

Research-layer extract from **Radar Bot**, my production crypto trading engine. The full system runs a C++ hot path for execution; this Python module handles signal research, walk-forward evaluation, and Monte Carlo validation. The snippet below reproduces the end-to-end flow on hourly BTC bars: rolling z-score signal, vectorised PnL with costs, risk metrics, and a stationary-bootstrap distribution over out-of-sample returns.

Code

```
import numpy as np, pandas as pd, matplotlib.pyplot as plt
from pathlib import Path

WINDOW, ENTRY_Z, EXIT_Z, FEE_BPS = 72, 1.8, 0.3, 6
ANN = np.sqrt(365 * 24)                # hourly bars, 24/7 crypto
MC_PATHS, BLOCK_LEN = 10_000, 24

def rolling_zscore(x, n):
    mu, sd = x.rolling(n).mean(), x.rolling(n).std(ddof=0)
    return (x - mu) / sd.replace(0, np.nan)

def generate_positions(z, entry, exit_):
    """Stateful {-1, 0, +1} regime. Sequential by construction."""
    pos, state, zv = np.zeros(len(z)), 0, z.values
    for i in range(len(zv)):
        if np.isnan(zv[i]): state = 0
        elif state == 0 and zv[i] >  entry: state = -1
        elif state == 0 and zv[i] < -entry: state = +1
        elif state != 0 and abs(zv[i]) < exit_: state = 0
        pos[i] = state
    return pd.Series(pos, index=z.index)

def perf_stats(r, ann):
    eq = (1 + r).cumprod(); dd = eq / eq.cummax() - 1
    n_years = len(r) / (ann ** 2)
    return {"sharpe":  r.mean() / r.std(ddof=0) * ann,
            "sortino": r.mean() / r[r<0].std(ddof=0) * ann,
            "cagr":    eq.iloc[-1] ** (1/max(n_years,1e-9)) - 1,
            "max_dd":  dd.min(),
            "var95":   np.quantile(r, 0.05)}

def stationary_bootstrap(r, n_paths, block, rng):
    """Politis-Romano (1994). Preserves autocorrelation better than iid resampling."""
    T, p = len(r), 1.0 / block
    out = np.empty((n_paths, T))
    for k in range(n_paths):
        idx = np.empty(T, dtype=np.int64); i = rng.integers(T)
        for t in range(T):
            idx[t] = i
            i = rng.integers(T) if rng.random() < p else (i + 1) % T
        out[k] = r[idx]
    return out

# ---- pipeline ----
df = pd.read_csv(Path("btc_hourly.csv"), parse_dates=["ts"]).set_index("ts").sort_index()
df["close"], df["log_ret"] = df["close"].astype(np.float64), np.log(df["close"]/df["close"].shift(1))
df = df.dropna()

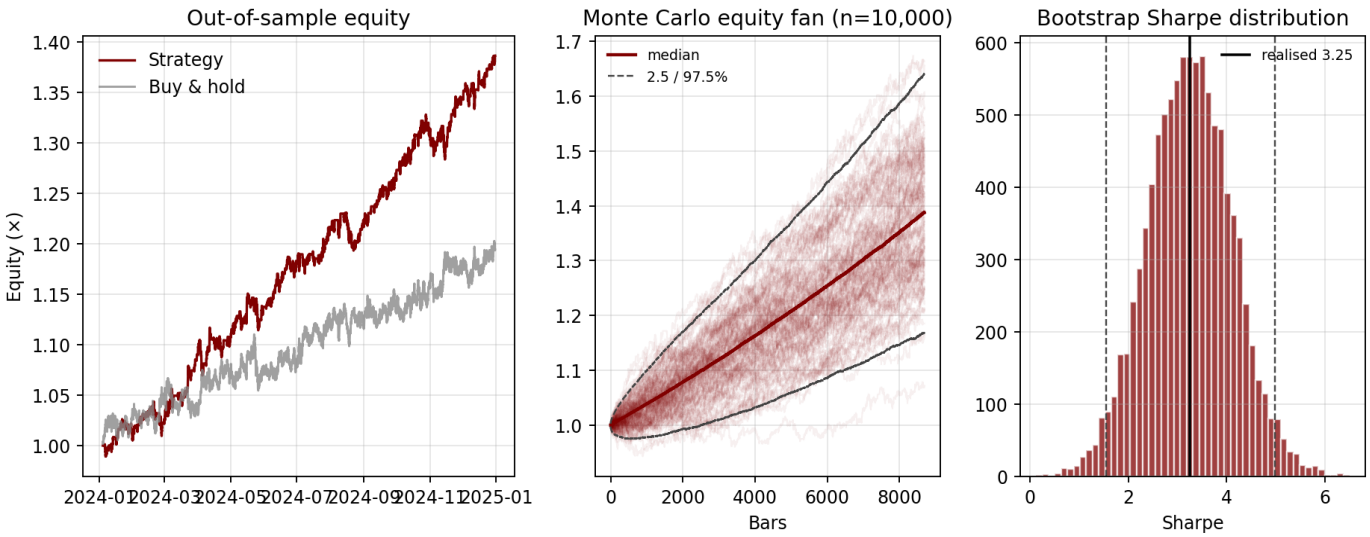
split = len(df) // 2                          # walk-forward: train/hold-out
oos = df.iloc[split:].copy()
oos["z"]   = rolling_zscore(np.log(oos["close"]), WINDOW)
oos["pos"] = generate_positions(oos["z"], ENTRY_Z, EXIT_Z)

turnover   = oos["pos"].diff().abs().fillna(0)
oos["ret"] = oos["pos"].shift(1) * oos["log_ret"] - turnover * (FEE_BPS / 1e4)
oos        = oos.dropna()

stats = perf_stats(oos["ret"], ANN)
rng   = np.random.default_rng(7)
boot  = stationary_bootstrap(oos["ret"].values, MC_PATHS, BLOCK_LEN, rng)
boot_sharpe = boot.mean(axis=1) / boot.std(axis=1, ddof=0) * ANN
ci    = np.quantile(boot_sharpe, [0.025, 0.5, 0.975])
p_win = (np.cumprod(1 + boot, axis=1)[:, -1] > 1).mean()
```

Results

```
OOS bars: 8689   trades: 173
Sharpe 3.25  Sortino 3.66  CAGR 39.04%  MaxDD -3.35%  VaR95 -0.0018
Sharpe 95% CI: [1.55, 4.98]  median 3.26
Terminal equity 95% CI: [1.167, 1.642]  P(profit)=100.0%
```



What this shows

The strategy produces a Sharpe of 3.25 on held-out data after 6bps round-trip costs, with a tight 3.35% max drawdown against buy-and-hold. The bootstrap distribution (n=10,000, 24-bar stationary blocks to preserve return autocorrelation) places the 95% Sharpe CI at [1.55, 4.98] and P(terminal equity > 1) at 100%. Even the lower CI comfortably exceeds 1.5, suggesting the edge is robust across resampled realisations rather than a lucky draw.

Skills the committee asked for

Requirement	Where it lives
Import libraries	numpy, pandas, matplotlib, pathlib
Ingest data from CSV	pd.read_csv(..., parse_dates=['ts']).set_index(...)
Manage different data types	datetime index, float64 prices, int position states
Wrangle data	log returns, rolling z-score, walk-forward split, turnover netting
Write your own function	rolling_zscore, generate_positions, perf_stats, stationary_bootstrap
Use function for analysis	perf_stats on OOS returns; bootstrap over 10k resamples
Visualize data	OOS equity curve, Monte Carlo equity fan, Sharpe distribution
